Abstract

Feature representations, both hand-designed and learned ones, are often hard to analyze and interpret, even when they are extracted from visual data. We propose a new approach to study image representations by inverting them with an up-convolutional neural network. We apply the method to shallow representations (HOG, SIFT, LBP), as well as to deep networks. For shallow representations our approach provides significantly better reconstructions than existing methods, revealing that there is surprisingly rich information contained in these features when combined with a strong prior. Inverting a deep network trained on ImageNet provides several insights into the properties of the feature representation learned by the network. Most strikingly, the colors and the rough contours of an image can be reconstructed from activations in higher network layers and even from the predicted class probabilities.

1. Introduction

A feature representation useful for pattern recognition tasks is expected to concentrate on properties of the input image which are important for the task and ignore the irrelevant properties of the input image. For example, hand-designed descriptors such as HOG [3] or SIFT [18], explicitly discard the absolute brightness by only considering gradients, precise spatial information by binning the gradients and precise values of the gradients by normalizing the histograms. Convolutional neural networks (CNNs) trained in a supervised manner [15, 14] are expected to discard information irrelevant for the task they are solving [29, 20, 23].

In this paper, we show how much information of an image can be retrieved from its feature representation in conjunction with a prior learned from natural images. We obtain further insights into the structure of the feature space, as we apply the inverse of the feature representation to perturbed feature vectors, to interpolations between two feature vectors, or to random feature vectors.

Figure 1: We train convolutional networks to reconstruct images from different feature representations. **Top row:** Input features. **Bottom row:** Reconstructed image. Reconstructions from HOG and SIFT are very realistic. Reconstructions from AlexNet preserve color and rough object positions even when reconstructing from higher layers.

The task of inverting a non-trivial feature representation $\Phi: \mathbb{R}^n \rightarrow \mathbb{R}^m$ is ill-posed. The dimensionality of the feature space is typically smaller than that of the input, and feature representations are designed or trained to be invariant to certain variations in the input image, such as noise, illumination changes, translations. This leads to mapping many inputs to the same, or virtually indistinguishable, feature vectors. However, all these solutions are not equally likely in real images. If we assume a natural image $x \in \mathcal{N}$ as input, the inversion can be regularized by imposing a natural image prior. Rather than manually defining such a prior, as in [20], we propose to learn it implicitly from natural images with a CNN. Such prior is much more powerful than a manually defined one. Hence, it allows for significantly more realistic image reconstructions.

We build upon the recently proposed up-convolutional architecture [6] that generates large images at low computational cost. The training is supervised: the input to the network is the feature representation of an image and the target is the image itself. The loss function is the Euclidean distance between the input image and its reconstruction from

the feature representation. We do not explicitly include a natural image prior into the loss, but to reconstruct the images of the training set the network must learn it.

We apply our inversion method to AlexNet [14], a convolutional network trained for classification on ImageNet, as well as to three widely used computer vision features: histogram of oriented gradients (HOG) [3, 7], scale invariant feature transform (SIFT) [18], and local binary patterns (LBP) [22]. The SIFT representation comes as a non-uniform, sparse set of oriented keypoints with their corresponding descriptors at various scales. This is an additional challenge for the inversion task. LBP features are not differentiable with respect to the input image. Thus, existing methods based on gradients of representations [20] could not be applied to them.

1.1. Related work

Our approach is related to a large body of work on inverting neural networks. These include works making use of backpropagation or sampling [16, 17, 19, 28, 10, 26] and, most similar to our approach, other neural networks [2]. However, only recent advances in neural network architectures allow us to invert a modern large convolutional network with another network.

Our approach is not to be confused with the DeconvNet [29], which propagates high level activations backward through a network to identify parts of the image responsible for the activation. In addition to the high-level feature activations, this reconstruction process uses extra information about maxima locations in intermediate max-pooling layers. This information was shown to be crucial for the approach to work [23]. A visualization method similar to DeconvNet is by Springenberg et al. [23], yet it also makes use of intermediate layer activations.

Mahendran and Vedaldi [20] invert a differentiable image representation Φ using gradient descent. Given a feature vector Φ_0 , they seek for an image x^* which minimizes a loss function. The loss is the Euclidean distance between Φ_0 and $\Phi(x)$ plus a regularizer enforcing a natural image prior. This method is fundamentally different from our approach in that it optimizes the difference between the feature vectors, not the image reconstruction error. Formally speaking, while [20] search for the inverse Φ_R^{-1} such that $\Phi(\Phi_R^{-1}(\phi)) \approx \phi$, we are interested in Φ_L^{-1} such that $\Phi_L^{-1}(\Phi(x)) \approx x$. The difference between these two approaches is especially pronounced when many images get mapped to similar feature vectors: while our method tries hard to distinguish between them, the method of [20] does not care much. Moreover, the approach of [20] involves optimization at test time, which requires computing the gradient of the feature representation and makes it relatively slow (the authors report 6s per image on a GPU). In contrast, the presented approach is only costly when training

the inversion network. Reconstruction from a given feature vector just requires a single forward pass through the network, which takes roughly 5ms per image on a GPU. Since it does not require gradients of the feature representation, it can also be applied to LBPs, as shown in this paper, or potentially to recordings from a real brain, somewhat similar to [21].

There has been research on inverting various traditional computer vision representations: HOG and dense SIFT [25], keypoint-based SIFT [27], Local Binary Descriptors [4], Bag-of-Visual-Words [12]. All these methods are either tailored for inverting a specific feature representation or restricted to shallow representations, while our method can be applied to any feature representation.

2. Feature representations

Shallow features. We invert three traditional computer vision feature representations: histogram of oriented gradients (HOG), scale invariant feature transform (SIFT), and local binary patterns (LBP). We decided to invert these features for a reason. There has been work on inverting HOG, so we can compare to existing approaches. LBP is interesting because it is not differentiable, and hence gradient-based methods cannot invert it. SIFT is a keypoint-based representation, so it is not so straightforward to apply a ConvNet to it.

For all three methods we use implementations from the *VLFeat* library [24] with the default settings. More precisely, we use the HOG version from Felzenszwalb et al. [7] with cell size 8, the version of SIFT which is very similar to the original implementation of Lowe [18] and the LBP version similar to Ojala et al. [22] with cell size 16. Before extracting the features we convert images to grayscale. More details can be found in the supplementary material.

AlexNet. We also invert the representation of the AlexNet network [14] trained on ImageNet, available at the *Caffe* [11] website.¹ Its architecture is briefly summarized in Table 1. Note that we distinguish between layers and processing steps. In what follows, when we say ‘output of the layer’, it means the output of the last processing step of this layer. For example, the output of the layer CONV1 would be the result after norm1. Please see [14] for more details on AlexNet.

3. Method

Denote by $\{x_i\}$ the training set and by $\Phi(x)$ the feature representation we aim to invert. We parameterize the inverse of Φ by an up-convolutional neural network $f(\phi, W)$ that takes a feature vector ϕ as an input and yields an image as output. We then optimize the weights W of the network

¹More precisely, we used CaffeNet, which is almost identical to the original AlexNet.

layer	CONV1		CONV2		CONV3	CONV4	CONV5		FC6		FC7		FC8
processing steps	conv1 relu1	mpool1 norm1	conv2 relu2	mpool2 norm2	conv3 relu3	conv4 relu4	conv5 relu5	mpool5	fc6 relu6	drop6	fc7 relu7	drop7	fc8
out size	55	27	27	13	13	13	13	6	1	1	1	1	1
out channels	96	96	256	256	384	384	256	256	4096	4096	4096	4096	1000

to minimize the squared Euclidean reconstruction error:

$$W^* = \arg \min_W \sum_i \|x_i - f(\Phi(x_i), W)\|_2^2. \quad (1)$$

In some cases we predict downsampled images to speed up computations. For HOG, LBP and SIFT, we compute the features based on grayscale versions of images, but then train the network to predict color images.

An up-convolutional layer, also often referred to as ‘de-convolutional’, is a combination of upsampling and convolution [6]. We upsample a feature map by a factor 2 by replacing each value by a 2×2 block with the original value in the top left corner and all other entries equal to zero.

We now briefly explain how we apply CNNs to different representations. Detailed network descriptions are provided in the supplementary material.

HOG and LBP. For an image of size $W \times H$, HOG and LBP features of an image form 3-dimensional arrays of sizes $\lceil W/8 \rceil \times \lceil H/8 \rceil \times 31$ and $\lceil W/16 \rceil \times \lceil H/16 \rceil \times 58$, respectively. We use similar CNN architectures for inverting both feature representations. The networks include a contracting part, which processes the input features through a series of convolutional layers with occasional stride of 2, resulting in a feature map 64 times smaller than the input image. Then the expanding part of the network again upsamples the feature map to the full image resolution by a series of up-convolutional layers.

Sparse SIFT. Running the SIFT detector and descriptor on an image gives a set of N keypoints, where the i -th keypoint is described by its coordinates (x_i, y_i) , scale s_i , orientation α_i , and a feature descriptor \mathbf{f}_i of dimensionality D . In order to apply a convolutional network, we arrange them on a grid. We split the image into cells of size $s \times s$ (we used $s = 4$ in our experiments), this yields $\lceil W/s \rceil \times \lceil H/s \rceil$ cells. In the rare cases when there are several keypoints in a cell, we randomly select one. We then assign a vector to each of the cells: a zero vector to a cell without a keypoint and a vector $(\mathbf{f}_i, x_i \bmod ds, y_i \bmod ds, \sin \alpha_i, \cos \alpha_i, \log s_i)$ to a cell with a keypoint. This results in a feature map \mathbf{F} of size $\lceil W/d \rceil \times \lceil H/d \rceil \times (D + 5)$. Then we apply a CNN to \mathbf{F} , as described above.

AlexNet. To reconstruct from each layer of AlexNet we trained a separate network. We varied the architecture of the generative networks as little as possible depending on the layer being inverted. In fact, we used just two

basic architectures: one for reconstructing from convolutional layers and one for reconstructing from fully connected layers. The network for reconstructing from fully connected layers contains three fully connected layers and 5 up-convolutional layers. The network for reconstructing from convolutional layers consists of three convolutional and several up-convolutional layers (the exact number depends on the layer to reconstruct from). Filters in all (up-)convolutional layers have 5×5 spatial size. After each layer we apply leaky ReLU nonlinearity with slope 0.2, that is, $r(x) = x$ if $x \geq 0$ and $r(x) = 0.2 \cdot x$ if $x < 0$.

Training details. We trained networks using a modified version of Caffe [11]. As training data we used the ImageNet [5] training set. We used the Adam [13] optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.999$ and mini-batch size 64. For most networks we found an initial learning rate $\lambda = 0.001$ to work well. We gradually decreased the learning rate towards the end of training. The duration of training depended on the network: from 15 epochs (passes through the dataset) for shallower networks to 60 epochs for deeper ones.

Quantitative evaluation. As a quantitative measure of performance we used the average normalized reconstruction error, that is the mean of $\|x_i - f(\Phi(x_i))\|_2/N$, where x_i is an example from the test set, f is the function implemented by the inversion network and N is a normalization coefficient equal to the average Euclidean distance between images in the test set. The test set we used for quantitative and qualitative evaluations is a subset of the ImageNet validation set.

4. Experiments: shallow representations

Figures 1 and 3 show reconstructions of several images from the ImageNet validation set. Normalized reconstruction error of different methods is shown in Table 2. Clearly, our method significantly outperforms existing approaches. This is to be expected, since our method explicitly aims to minimize the reconstruction error.

Colorization. As mentioned above, we compute the fea-

Hoggles [25]	HOG^{-1} [20]	HOG our	SIFT our	LBP our
0.61	0.63	0.24	0.28	0.38

Table 2: Normalized image reconstruction error of different methods.

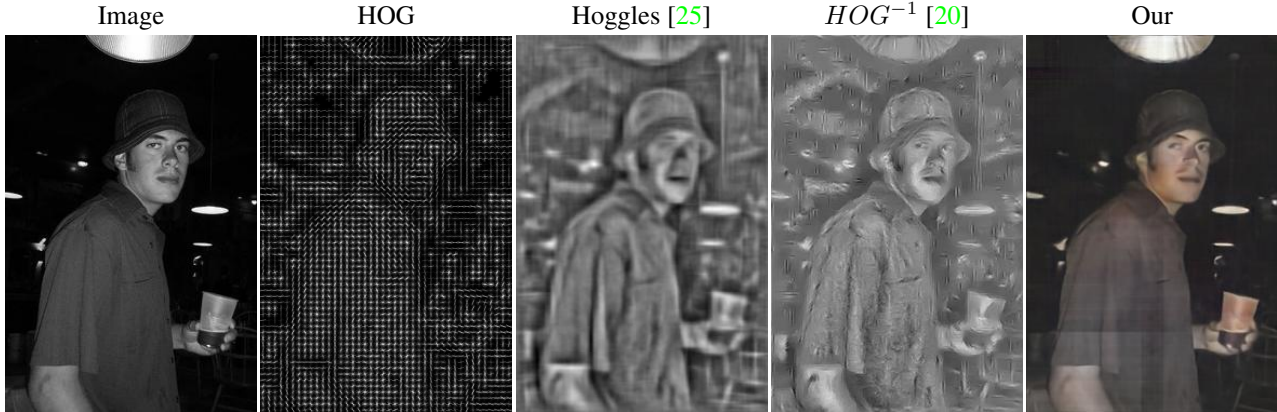

Figure 2: Reconstructing an image from its HOG descriptors with different methods.

tures based on grayscale images, but the task of the network is to reconstruct the color image. The features do not contain any color information, so to predict colors the network has to analyze the content of the image and make use of a prior it learned during training. It does successfully learn to do this, as can be seen in Figures 1 and 3. Quite often the colors are predicted correctly, especially for sky, sea, grass, trees. In other cases, the network cannot predict the color (for example, people in the top row of Figure 3) and leaves some areas gray. Occasionally the network predicts the wrong color, such as in the bottom row of Figure 3.

HOG. Figure 2 shows an example image, its HOG representation, the results of inversion with existing methods [25, 20] and with our approach. Most interestingly, the network is able to reconstruct the overall brightness of the image very well, for example the dark regions are reconstructed dark. This is quite surprising, since the HOG descriptors are normalized and should not contain information about absolute brightness.

Since normalization is always performed with a smoothing ‘epsilon’, one might imagine that some information about the brightness is present even in the normalized features. We checked that the network does not make use of this information: multiplying the input image by 10 or 0.1 hardly changes the reconstruction. Therefore, we hypothesize that the network reconstructs the overall brightness by 1) analyzing the distribution of the HOG features (if in a cell there is similar amount of gradient in all directions, it is probably noise; if there is one dominating gradient, it must actually be in the image), 2) accumulating gradients over space: if there is much black-to-white gradient in one direction, then probably the brightness in that direction goes from dark to bright and 3) using semantic information.

SIFT. Figure 4 shows an image, the detected SIFT keypoints and the resulting reconstruction. There are roughly 3000 keypoints detected in this image. Although made from a sparse set of keypoints, the reconstruction looks very nat-

Figure 3: Inversion of shallow image representations. Note how in the first row the color of grass and trees is predicted correctly in all cases, although it is not contained in the features.

Figure 4: Reconstructing an image from SIFT descriptors with different methods. (a) an image, (b) SIFT keypoints, (c) reconstruction of [27], (d) our reconstruction.

ural, just a little blurry. To achieve such a clear reconstruction the network has to properly rotate and scale the descriptors and then stitch them together. Obviously it successfully learns to do this.

For reference we also show a result of another existing method [27] for reconstructing images from sparse SIFT descriptors. The results are not directly comparable: while we use the SIFT detector providing circular keypoints, Weinzaepfel et al. [27] use the Harris affine keypoint detector which yields elliptic keypoints, and the number and the locations of the keypoints may be different from our case. However, the rough number of keypoints is the same, so a qualitative comparison is still valid.

5. Experiments: AlexNet

We applied our inversion method to different layers of AlexNet and performed several additional experiments to better understand the feature representations. More results are shown in the supplementary material.

5.1. Reconstructions from different layers

Figure 5 shows reconstructions from various layers of AlexNet. When using features from convolutional layers, the reconstructed images look very similar to the input, but lose fine details as we progress to higher layers. There is an obvious drop in reconstruction quality when going from CONV5 to FC6. However, the reconstructions from higher convolutional layers and even fully connected layers preserve color and the approximate object location very well.

Figure 7: Average normalized reconstruction error depending on the network layer.

Reconstructions from FC7 and FC8 still look similar to the input images, but blurry. This is in strong contrast with the results of [20], as shown in Figure 6. While their reconstructions are sharper, the color and position are completely lost in reconstructions from higher layers. This is not surprising, as [20] aim to match the feature representations, not the images.

For quantitative evaluation before computing the error we up-sample reconstructions to input image size with bilinear interpolation. Error curves shown in Figure 7 support the conclusions made above. When reconstructing from FC6, the error is roughly twice as large as from CONV5. Even when reconstructing from FC8, the error is fairly low because the network manages to get the color and the rough placement of large objects in images right. For lower layers, the reconstruction error of [20] is still much higher than of our method, even though visually the images look somewhat sharper. The reason is that the color and the precise placement of small details do not perfectly match, which results in a large overall error. This is because the method of [20] was not designed to achieve low reconstruction error in the input image space.

We use squared Euclidean distance in RGB space as loss when training the CNNs. While this is the most obvious and interpretable error measure, it is known to favor over-smoothed solutions. We suppose that using a different loss could result in visually even better reconstructions from deep CNN layers.

5.2. Autoencoder training

Our reconstruction network can be interpreted as the decoder of the representation encoded by AlexNet. The difference to an autoencoder is that the encoder part stays fixed and only the decoder is optimized. For comparison we also trained autoencoders with the same architecture as our re-

construction nets, i.e., we also allowed the training to fine-tune the parameters of the AlexNet part.

With the autoencoders we can check whether the results of inverting higher layers of AlexNet look blurred simply because the networks we trained are quite deep and the training may not have succeeded, or because the representation in higher layers is too compressed. This is not the case. As shown in Figure 7, autoencoder training yields much lower reconstruction errors when reconstructing from higher layers. Also the qualitative results in Figure 6 show much better reconstructions with autoencoders. Even from CONV5 features, the input image can be reconstructed almost perfectly. When reconstructing from fully connected layers, the autoencoder results get blurred, too, due to the compressed representation, but by far not as much as with the fixed AlexNet weights. The gap between the autoencoder training and the training with fixed AlexNet gives an estimate of the amount of image information lost due to the training objective of the AlexNet, which is not based on reconstruction quality.

An interesting observation with autoencoders is that the reconstruction error is quite high even when reconstructing from CONV1 features, and the best reconstructions were actually obtained from CONV4. Our explanation is that the convolution with stride 4 and consequent max-pooling in CONV1 loses much information about the image. To decrease the reconstruction error, it is beneficial for the network to slightly blur the image instead of guessing the details. When reconstructing from deeper layers, deeper networks can learn a better prior resulting in slightly sharper images and slightly lower reconstruction error. For even deeper layers, the representation gets too compressed and the error increases again. We observed (not shown in the paper) that without stride 4 in the first layer, the reconstruction error of autoencoders got much lower.

5.3. Case study: Colored apple

We performed a simple experiment illustrating how the color information influences classification and how it is preserved in the high level features. We took an image of a red apple (Figure 8 top left) from Flickr and modified its hue to make it green or blue. Then we extracted AlexNet FC8 features of the resulting images. Remind that FC8 is the last layer of the network, so the FC8 features, after application of softmax, give the network’s prediction of class probabilities. The largest activation, hence, corresponds to the network’s prediction of the image class. To check how class-dependent the results of inversion are, we passed three versions of each feature vector through the inversion network: 1) just the vector itself, 2) all activations except the 5 largest ones set to zero, 3) the 5 largest activations set to zero.

This leads to several conclusions. First, color clearly can

Figure 9: Reconstructions from different layers of AlexNet with disturbed features.

Figure 8: The effect of color on classification and reconstruction from layer FC8. Left to right: input image, reconstruction from FC8, reconstruction from 5 largest activations in FC8, reconstruction from all FC8 activations except the 5 largest ones. Below each row the network prediction and its confidence are shown.

be very important for classification, so the feature representation of the network has to be sensitive to it, at least in some cases. Second, the color of the image can be precisely reconstructed even from FC8 or, equivalently, from the predicted class probabilities. Third, the reconstruction quality does not depend much on the top predictions of the network but rather on the small probabilities of all other classes. This is consistent with the 'dark knowledge' idea of [9]: small probabilities of non-predicted classes carry more information than the prediction itself.

5.4. Robustness of the feature representation

We have shown that high level feature maps preserve rich information about the image. How is this information represented in the feature vector? It is difficult to answer this question precisely, but we can gain some insight by perturbing the feature representations in certain ways and observing the result. If perturbing the features in a certain way

does not change the reconstruction much, then the perturbed property is not important. For example, if setting a non-zero feature to zero does not change the reconstruction, then this feature will not carry information useful for the reconstruction.

We applied binarization and dropout. To binarize the feature vector, we kept the signs of all entries and set their absolute values to a fixed number, selected such that the Euclidean norm of the vector remained unchanged (we tried several other strategies, and this one led to the best result). For all layers except FC8, feature vector entries are non-negative, hence, binarization just sets all non-zero entries to a fixed positive value. To perform dropout, we randomly set 50% of the feature vector entries to zero and then normalize the vector to keep its Euclidean norm unchanged (again, we found this normalization to work best). Qualitative results of these perturbations of features in different layers of AlexNet are shown in Figure 9. Quantitative results are shown in Figure 7. Surprisingly, dropout leads to larger decrease in reconstruction accuracy than binarization, even in the layers where it had been applied during training. In layers FC7 and especially FC6, binarization hardly changes the reconstruction quality at all. Although it is known that binarized ConvNet features perform well in classification [1], it comes as a surprise that for reconstructing the input image the exact values of the features are not important. In FC6 virtually all information about the image is contained in the binary code given by the pattern of non-zero activations. Figures 7 and 9 show that this binary code only emerges when training with the classification objective and dropout, while autoencoders are very sensitive to perturbations in the features.

To test the robustness of this binary code, we applied binarization and dropout together. We tried dropping out 50% random activations or 50% least non-zero activations and then binarizing. Dropping out the 50% least activations reduces the error much less than dropping out 50% random activations and is even better than not applying any dropout for most layers. However, layers FC6 and FC7 are the most interesting ones: here dropping out 50% random activations

Figure 10: Interpolation between the features of two images.

decreases the performance substantially, while dropping out 50% least activations only results in a small decrease. Possibly the exact values of the features in FC6 and FC7 do not affect the reconstruction much, but they estimate the importance of different features.

5.5. Interpolation and random feature vectors

Another way to analyze the feature representation is by traversing the feature manifold and by observing the corresponding images generated by the reconstruction networks. We have seen the reconstructions from feature vectors of actual images, but what if a feature vector was not generated from a natural image? In Figure 10 we show reconstructions obtained with our networks when interpolating between feature vectors of two images. It is interesting to see that interpolating CONV5 features leads to a simple overlay of images, but the behavior of interpolations when reconstructing from FC6 is very different: images smoothly morph into each other. More examples, together with the results for autoencoders, are shown in the supplementary material.

Another analysis method is by sampling feature vectors randomly. Our networks were trained to reconstruct images given their feature representations, but the distribution of the feature vectors is unknown. Hence, there is no simple principled way to sample from our model. However, by assuming independence of the features (a very strong and wrong assumption!), we can approximate the distribution of each dimension of the feature vector separately. To this end we simply computed a histogram of each feature over a set of 4096 images and sampled from those. We ensured that the sparsity of the random samples is the same as that of the actual feature vectors. This procedure led to low contrast images, perhaps because by independently sampling each dimension we did not introduce interactions between the features. Multiplying the feature vectors by a constant factor $\alpha = 2$ increases the contrast without affecting other

Figure 11: Images generated from random feature vectors of top layers of AlexNet.

properties of the generated images.

Random samples obtained this way from four top layers of AlexNet are shown in Figure 11. No pre-selection was performed. While samples from CONV5 look much like abstract art, the samples from fully convolutional layers are much more realistic. This shows that the networks learn a natural image prior that allows them to produce realistically looking images from random feature vectors. We found that a much simpler sampling procedure of fitting a single shifted truncated Gaussian to all feature dimensions produces qualitatively very similar images. These are shown in the supplementary material together with images generated from autoencoders, which look much less like natural images.

We did not perform a quantitative analysis, since we are not aware of existing generative models of ImageNet and a proper estimation of the likelihood of the generated data is a difficult task by itself.

6. Conclusions

We have proposed to invert image representations with up-convolutional networks and have shown that this yields more or less accurate reconstructions of the original images, depending on the overall size of the feature representation. The natural image priors learned by the networks are very strong and even allow the retrieval of information that is obviously lost in the feature representation, such as color or brightness. The reconstruction method is very fast at test time and does not require the gradient of the feature representation to be inverted. Therefore, it can be applied to virtually any image representation.

Application of our method to the representations learned by the AlexNet convolutional network leads to several conclusions: 1) Features from all layers of the network, including the final FC8 layer, preserve the precise colors and the rough position of objects in the image; 2) In higher layers, almost all information about the input image is contained in the pattern of non-zero activations, not their precise values;

3) In the layer FC8, most information about the input image is contained in small probabilities of those classes that are not in top-5 network predictions.

Acknowledgements

We acknowledge funding by the ERC Starting Grant VideoLearn (279401). We are grateful to Aravindh Mahendran for sharing with us the reconstructions achieved with the method of Mahendran and Vedaldi [20]. We thank Jost Tobias Springenberg for useful comments.

Appendix A

We performed preliminary experiments with another approach to inverting visual representations with convolutional networks. Namely, instead of Euclidean distance we minimize the distance in the feature space between the features of the reconstruction and the features of the original image. This is similar to Mahendran and Vedaldi [20]. However, instead of a hand-designed natural prior we learn a prior using Generative Adversarial Networks (GAN) framework [8]. This results in much more natural reconstructions than those of Mahendran and Vedaldi. A comparison of different inversion methods is shown in Figures 12 and 13.

Supplementary material

Network architectures Tables 3-7 show the architectures of networks we used for inverting different features. After each fully connected and convolutional layer there is always a leaky ReLU nonlinearity. Networks for inverting HOG and LBP have two streams. Stream A compresses the input features spatially and accumulates information over large regions. We found this crucial to get good estimates of the overall brightness of the image. Stream B does not compress spatially and hence can better preserve fine local details. At one points the outputs of the two streams are concatenated and processed jointly, denoted by “J”.

Layer	Input	InSize	K	S	OutSize
convA1	LBP	$16 \times 16 \times 58$	5	2	$8 \times 8 \times 256$

Table 7: Network for reconstructing from AlexNet FC8 features.

Figure 14: Inversion of shallow image representations.

Shallow features details As mentioned, in the paper, for all three methods we use implementations from the *VLFeat* library [24] with the default settings. We use the Felzenszwalb et al. version of HOG with cell size 8. For SIFT we used 3 levels per octave, the first octave was 0 (corresponding to full resolution), the number of octaves was set automatically, effectively searching keypoints of all possible sizes.

The LBP version we used works with 3×3 pixel neighborhoods. Each of the 8 non-central bits is equal to one if the corresponding pixel is brighter than the central one. All possible 256 patterns are quantized into 58 patterns. These include 56 patterns with exactly one transition from 0 to 1 when going around the central pixel, plus one quantized pattern comprising two uniform patterns, plus one quantized pattern containing all other patterns. The quantized LBP patterns are then grouped into local histograms over cells of 16×16 pixels.

Experiments: shallow representations Figure 14 shows several images and their reconstructions from HOG, SIFT and LBP. HOG allows for the best reconstruction, SIFT slightly worse, LBP yet slightly worse. Colors are often reconstructed correctly, but sometimes are wrong, for example in the last row. Interestingly, all network typically agree on estimated colors.

Experiments: AlexNet We show here several additional figures similar to ones from the main paper. Reconstructions from different layers of AlexNet are shown in Figure 15. Figure 16 shows results illustrating the ‘dark knowledge’ hypothesis, similar to Figure 8 from the main paper. We reconstruct from all FC8 features, as well as from only 5 largest ones or all except the 5 largest ones. It turns out that the top 5 activations are not very important.

Figure 17 shows images generated by activating single neurons in different layers and setting all other neurons to zero. Particularly interpretable are images generated this way from FC8. Every FC8 neuron corresponds to a class. Hence the image generated from the activation of, say, “apple” neuron, could be expected to be a stereotypical apple. What we observe looks rather like it might be the average of all images of the class. For some classes the reconstructions are somewhat interpretable, for others – not so much.

Qualitative comparison of reconstructions with our method to the reconstructions of [20] and the results with AlexNet-based autoencoders is given in Figure 18.

Reconstructions from feature vectors obtained by interpolating between feature vectors of two images are shown in Figure 19, both for fixed AlexNet and autoencoder training. More examples of such interpolations with fixed AlexNet are shown in Figure 20.

As described in section 5.5 of the main paper, we tried two different distributions for sampling random feature activations: a histogram-based and a truncated Gaussian. Figure 21 shows the results with fixed AlexNet network and truncated Gaussian distribution. Figures 22 and 23 show images generated with autoencoder-trained networks. Note that images generated from autoencoders look much less realistic than images generated with a network with fixed AlexNet weights. This indicates that reconstructing from AlexNet features requires a strong natural image prior.

Figure 15: Reconstructions from different layers of AlexNet.

Figure 16: Left to right: input image, reconstruction from fc8, reconstruction from 5 largest activations in FC8, reconstruction from all FC8 activations except 5 largest ones.

Figure 17: Reconstructions from single neuron activations in the fully connected layers of AlexNet. The FC8 neurons correspond to classes, left to right: kite, convertible, desktop computer, school bus, street sign, soup bowl, bell pepper, soccer ball.
